ABSTRACT: Travertines are found in ophiolite massifs in association with bicarbonate-depleted hyperalkaline spring waters (pH up to 11.9), in contrast with most continental carbonates (e.g., travertine, tufa, speleothems) that precipitate from calcium bicarbonate-enriched waters. Here travertines formed from bicarbonate-depleted hyperalkaline spring water were subjected to a multidisciplinary and multi-scale approach to evaluate their potential as proxies of past climatic records and sequestration of atmospheric CO2.

The characterization of continental carbonate is of primary interest because of their ability to preserve paleoenvironmental data. The petrofacies resulting from a complex and dynamic interplay of physical, chemical, and biological activity (e.g., Pentecost 2005) and reference therein; Fouke 2011; Gandin and Capezzuoli 2014; Arenas et al. 2014; Capezzuoli et al. 2014). The characterization of continental carbonate is of growing interest because of their ability to preserve paleoenvironmental and paleoclimatic information at the time of their formation.

Overall, continental carbonates form predominantly at ambient temperature from calcium bicarbonate-enriched (Ca-CO32−) type waters. Alkalinity is derived either from dissolution of carbonate minerals, CO2 thermally generated in the deep Earth’s crust (Pentecost and Viles 1994; Pentecost 2005).

TRAVERTINES ASSOCIATED WITH HYPERALKALINE SPRINGS: EVALUATION AS A PROXY FOR PALEOEENVIRONMENTAL CONDITIONS AND SEQUESTRATION OF ATMOSPHERIC CO2

INTRODUCTION

Continental carbonates (e.g., speleothems, calcrete, lacustrine limestone, travertine, calcareous tufa, and tufa) are characterized by specific petrofacies resulting from a complex and dynamic interplay of physical, chemical, and biological activity (e.g., Pentecost 2005 and reference therein; Fouke 2011; Gandin and Capezzuoli 2014; Arenas et al. 2014; Capezzuoli et al. 2014). The characterization of continental carbonate is of growing interest because of their ability to preserve paleoenvironmental and paleoclimatic information at the time of their formation.

For two sites, the bulk chemical signature of travertines (Mg, Ca, and Sr wt%) are consistent with “prior calcite precipitation” (PCP) processes and thus likely records the environmental conditions at the time of their formation. However, for the third site, the trace-element concentrations in the various carbonate fabrics indicate some recrystallization. Constant δ18O values indicate that hydration and hydroxylation reactions completely buffer the oxygen isotope composition of the water (equilibrium state) from which a paleo-temperature can be estimated. In contrast, δ13C values reflect potential carbon sources, either from surface runoff waters or atmospheric CO2.

Within the framework of continental carbonate, calcium carbonate formation in bicarbonate-depleted hyperalkaline environments results in a linear co-variation of δ18O and δ13C values and defines a unique and distinctive stable-isotope field on a δ18O–δ13C plot, in contrast to carbonates formed in more typical bicarbonate-enriched environments. Moreover, the combined variations in δ18O, δ13C, and 87Sr/86Sr between laminae document the changes in the paleo-activity of hyperalkaline spring and surface runoff waters on the time scale of formation. The 87Sr/86Sr ratio represents a tracer for quantifying surface runoff water contribution. Furthermore, the amount of CO2 sequestered in travertine has been estimated following different scenarios of formation. The calculated CO2 sequestered for these deposits ranges from 9 kgCO2 yr−1 to 522 kgCO2 yr−1.

Alternatively, continental carbonates can be associated with hyperalkaline thermal springs located in ophiolite massifs, where circulating groundwaters interact with deep crustal rock and are typically depleted in dissolved inorganic carbon (DIC, e.g., Oman: Neal and Stanger 1983, Chavagnac et al. 2013a; New Caledonia: Launay and Fontes 1985, Monnin et al. 2014; Philippines: Abrajano et al. 1988). In this case, the serpentinization process has led to the conversion of initial Mg-HCO3 type waters into Ca-OH type hyperalkaline waters depleted both in DIC and Mg but enriched in Ca (Barnes et al. 1967; Barnes and O’Neil 1969; Barnes et al. 1978; Neal and Stanger 1984; Bruni et al. 2002; Cipollini et al. 2004; Sader et al. 2007; Kelemen and Matter 2008; Chavagnac et al. 2013b; Monnin et al. 2014). Precipitation of calcium carbonate from hyperalkaline spring waters is possible only if carbonate ions are available which is typically accomplished in two ways: 1) mixing between DIC-depleted hyperalkaline waters and DIC-rich surface runoff waters, and/or...
2) via diffusion and dissolution of atmospheric $\text{CO}_2$ into spring waters. As a result, the conditions leading to calcium carbonate formation in hyperalkaline springs is fundamentally different from carbonates that precipitate from bicarbonate-rich waters. However, thus far little is known on the reliability of these deposits as a proxy for past climatic records.

The purpose of this study is to provide a comprehensive and detailed study of three calcium carbonate deposits formed at DIC-depleted hyperalkaline springs in the Oman ophiolite. The objectives are 1) to assess the relationship between the petrologic features and fabrics and the geochemical and isotopic signatures, and 2) to discuss the potential of these deposits as proxies for the past climatic record and sequestration of atmospheric $\text{CO}_2$.

**BACKGROUND**

**General Spring Characteristics and Nomenclature**

The general characteristics of carbonate deposits collected in Oman can be summarized as follows:

1) They are associated with warm-temperature (20–65°C) hyperalkaline springs (pH ranges from 10 to 11.9) extremely depleted in Mg and DIC; the springs are preferentially located near two major structural discontinuities, i.e., the basal thrust plane (the contact between the peridotitic mantle section and the underlying sedimentary and metamorphic rocks) and the “paleo-Moho” (the contact between the peridotitic mantle section and the overlying gabbroic crustal section) (Neal and Stanger 1984; Pauckert et al. 2012; Chavagnac et al. 2013a).
2) Gas emissions at these springs are essentially composed of $\text{H}_2$ and $\text{CH}_4$ without any $\text{CO}_2$ (Sano et al. 1993; Bouland et al. 2013).
3) Mineral assemblage forming at spring discharge is essentially composed of calcite and aragonite (Chavagnac et al. 2013b).
4) Climatic conditions, e.g., arid or wet seasons, influence the formation rates and the morphologies of the carbonate deposits (Clark and Fontes 1990; Clark et al. 1992).

Over the last 20 years, classification and definition of continental carbonates have evolved based on lithological, petrological, geochemical, and isotopic characteristics (e.g., Capuzzoli et al. 2014; Gandin and Capuzzoli 2008; Pentecost 2005; Ford and Pedley 1996; Pentecost and Viles 1994).

Based on the most recent classification of Capuzzoli et al. (2014), the Oman carbonate deposits share characteristics that are indicative of both travertine and tufa deposits, i.e., “calcareous tufa” or “travertina.” However, their formation is directly linked to the activity of hyperalkaline waters, which testifies to a hydrothermal origin, i.e., a closer link to travertine terminology. Therefore, we refer to these deposits as travertine in agreement with previous publications (Clark and Fontes 1990; Clark et al. 1992; Mervine et al. 2014).

**Geological Context**

The Oman ophiolite is one of the largest and best-preserved sections of oceanic lithosphere (30,000 km²) exposed on land (Coleman 1981), (Fig. 1). The ophiolite is composed of two major lithological units, the mantle section, and the crustal section. The mantle section rests on top of a metamorphic, amphibolitic sole, itself resting on sedimentary rocks (carbonates, sandstones, and radiolarites) (e.g., Coleman 1981). It is formed mostly by variably serpentinized residual mantle harzburgites and dunites. Mafic to felsic intrusive lithologies (pyroxenites, wehrlites, troctolites, gabbros, tonalities) are a minor although ubiquitous constituent of the mantle section (Boudier and Coleman 1981; Ceuleneer et al. 1996; Amri et al. 1996; Python and Ceuleerne 2003). The crustal section, which overlies the mantle section, is more heterogeneous in terms of lithology, including ultramafic and gabbroic cumulates (Juteau et al. 1988; Abily and Ceuleneer 2013), granitic differentiates, and extrusive rocks (diabase dikes and pillow lavas) (Pallister and Hopson 1981; Alabaster et al. 1982; Amri et al. 1996).

At present, alteration of the ultramafic rocks through serpentinization reactions is driven by percolation of ancient and/or modern meteoric waters through fractures (Chavagnac et al. 2013a). Serpentinization reactions lead to the formation of hyperalkaline springs (25 to 40°C; Chavagnac et al. 2013a), which are numerous over the entire ophiolite belt and associated with travertine deposits (Neal and Stanger 1984; Kelemen et al. 2011; Chavagnac et al. 2013a; Mervine et al. 2014) (Figs. 1, 2).

**Climate of Oman**

The ophiolite crops out in the Northern Oman Mountains, located at the southeastern horn of the Arabian Peninsula (22–24°N). The climatic conditions are typical of a dry tropical area, with maximum air temperature ranging between 20 and 35°C during winter and >40°C in summer. The climate of the northeastern side of the mountain faces the Gulf of Oman and has some marine influence, whereas the southwestern side faces the Arabian Sands and is predominantly continental. The present-day average rainfall on the Northern Oman Mountains is on the order of 100 mm yr⁻¹ (Clark and Fontes 1990) and is influenced by two sources of precipitation: the Mediterranean Sea and the Indian Ocean. These two influences define a boundary called the Inter-Tropical Convergence Zone (ITCZ). The ITCZ varies seasonally along a north to south gradient. The Oman hydrology is highly variable because of the rainfall intensity variation and evaporation rates (Kwarteng et al. 2009).

**Paleoclimate Records of Oman**

Over longer timescales, paleoclimate studies on various materials (speleothems, lake sediments, and travertine) have revealed an alternation of humid and arid periods in Oman (Clark and Fontes 1990; Clark et al. 1992; Fleitmann et al. 2003; Fleitmann et al. 2004; Fleitmann et al. 2007; Fuchs and Buurkert 2008; Mervine et al. 2014). ¹⁴C dating methods, geochemistry, and stable-isotope (C and O) signatures were used to determine the timespan during which precipitation intensity had varied. For example, Fleitmann et al. (2003) linked the temporal δ¹⁸O variations of the precipitation recorded in speleothems (between −12 and −4‰) from Hoti cave (Oman) to the ITCZ shifts. Typically, previous results concentrated their effort on either geochemical features or petrological ones, rather than a combination of the two. Such observations are, however, crucial to elucidate the causal-consequence link between climate change and travertine morphology.

**SAMPLES AND METHODS**

Among a large series of travertine sites visited during three field campaigns (December 2008, January 2010, and January 2011), three sites were selected from hyperalkaline springs for which geological setting, chemical composition of hyperalkaline spring waters, gas emissions, and mineralogical assemblages have been carefully studied (Neal and Stanger 1984; Weyhenmeyer et al. 2002; Pauckert et al. 2012; Chavagnac et al. 2013a; Chavagnac et al. 2013b; Boulart et al. 2013; Mervine et al. 2014) (Fig. 1, Table 1) and best elucidate the different styles of carbonate precipitation. The samples were sawn with a diamond blade perpendicular to the lamination for microscopic-scale description. In addition, we used a micro-dremel to powder each lamina of samples 32 and 33, which were identified in microscopic observations (Fig. 3). To decipher whether travertine formed in a DIC-depleted environment constitutes a potential proxy of past climate variability, each sample was consequently characterized using various analytical techniques (details are reported in the Appendix Supplementary Material). We summarize their usefulness below:
Scanning electron microscopy (SEM) coupled with energy-dispersive spectroscopy (EDS) to identify chemical changes in the sample, based on code color imaging of chemical elements on thin-section areas.

Raman analysis and cathodoluminescence in order to determine calcium carbonate polymorphs from thin sections.

Electron microprobe analyses to detect and observe the repartition of substituted elements into the carbonates, such as magnesium (Mg) and strontium (Sr).

Oxygen and carbon isotope compositions were conducted to identify precipitation mechanisms and to characterize mixing processes.

$^{87}\text{Sr}/^{86}\text{Sr}$ isotope composition in order to quantify the mixing proportion between surface runoff and hyperalkaline spring waters that control the formation of travertine.

RESULTS

Site Description and Petrographic Analysis

In the first section of this paper, we describe each sampling site following the concept of sedimentary depositional facies (Fouke et al. 2001; Veysey et al. 2008; Fouke 2011) together with the main microscopic observations. In the following sections, we present the stable-isotope and radiogenic-isotope compositions from two of the sites.

“Mamy Nova” Site (Sample 28)

Site “Mamy Nova” is located in the wadi Zabyn, running through the Fizh massif (Fig. 1). The local topographic and geological setting corresponds to a mixing area between runoff and groundwaters that interacted with mantle peridotites on their way to the spring, although the main discharge itself lies on a gabbroic substratum. However, no sedimentary and metamorphic rocks are found in wadi Zabyn upstream from spring waters, which run exclusively in the mantle harzburgites. In the valley bottom, terrace deposits composed of cemented gravel bars are partially preserved, topping the gabbroic substratum. Both terrace and substratum are incised by the stream flow. The hyperalkaline spring discharge is located 1 to 2 m above the surface waters and emerges from a fractured zone running through the lower crustal section (Table 1; Fig. 2). Modern to ancient carbonate deposits occur from the spring discharge area over a distance of 1 km along the surface waters. Carbonate encrustation around gravels can be observed in the stream bottom. Small-scale (10 cm high) step-shaped micro-terracettes are present in the channel facies.
Sample 28 was taken from a carbonate gravel bar, which consists of a conglomerate of ultramafic rocks partially cemented by calcium carbonate. Pores are partially filled with detrital material consisting of a mixture of micritic allochems (clotted peloids partially cemented or redissolved), micrite, clays, and ultramafic fragments (Fig. 4A). Precipitation of carbonates occurred in the vadose zone, as suggested by the presence of aragonite microstalactic cement in some pores and discontinuous \( \sim 100\)-\( \mu \)m-thick drusy calcite cement that precipitated around the pores (Fig. 4B, C, D). Si- and Mg-rich clavate (10–25 \( \mu \)m in diameter and rich in organic matter) that underline a growth stage of the drusy isopachous sparite, as
well as the presence of aragonite needle-like features topped by a Si- and Mg-rich film (Fig. 4B).

**“Gravière” Site (Sample 32)**

At this site, the substratum of the hyperalkaline spring is located close to the boundary between mantle peridotites and lower crustal gabbroic cumulates. Meteoric waters travel through a large drainage system originating in the sedimentary and metamorphic rocks of the Saih Hatat and running through mantle peridotites (Table 2; Fig. 1). The valley is partially filled with highly cemented gravel bars that are incised by stream flow and partially covered by un cemented modern gravels. The hyperalkaline spring emerges on cemented gravel bars, where it mixes with the surface runoff waters (Fig. 2). At the spring discharge area, a modern carbonate deposit can be observed covering the stream bottom. Sample 32 was taken in the channel facies where the wadi Mansah and the hyperalkaline spring mix (Fig. 2). A green algae and/or bacterial mat covers the modern surface of the carbonate deposit in the channel facies (Fig. 2).

On a macroscopic scale, the sample is composed of a succession of 13 laminae exhibiting distinctive coloration, mineralogy, fabrics, and porosity (Fig. 5). The observations are summarized in Table 2. The sample displays a very complex spatial organization, with an alternation of light-, intermediate-, and dark-gray layers (Fig. 5). The laminae are composed of gothic-arch calcite, crystallized aragonite bushes, drusy calcite cement (Fig. 5, zones A and B), a Mg-, and Si-rich organic material (Fig. 5, zones A, B, D, and E) that contains also Al, dark-gray spheroids (Fig. 5, zone C), and micro-spheroids embedded in Mg-, Al-, and Si-rich organic material (Fig. 5, zone D). Large pores are also filled with drusy calcite cement (Fig. 5, zone C).

**“Irma” Site (Sample 33)**

The “Irma” site is located along the foothills of the Samail Massif in mantle peridotites overlying the sedimentary rocks of the Hawasina...
Formation and the greenschists and amphibolites of the metamorphic sole (Fig. 1). The local drainage system is located entirely within highly serpentinized mantle peridotites. The site itself is a large kilometer-wide terrace characterized by a layer of recent travertine several meters thick. There is no obvious surface runoff, implying that the precipitation of calcium carbonate takes up carbon from atmospheric CO₂ (Table 2; Fig. 2). Deposits form successive pools separated by aprons around and downstream of the hyperalkaline spring (Fig. 2).

Sample 33 was collected in the flowing hyperalkaline spring. It consists of calcite raft (sparite) deposits alternating with more organic-rich layers of vuggy calcite (micrite) displaying a laminoid-fenestral fabric (type LF-A according to Flügel (2004); Fig. 6A, B). Sparite overgrowths are observed on both sides of the rafts (Fig. 6D). Ultramafic detrital particles may occur between rafts (Fig. 6C).

**Chemical Composition of Carbonate Fabrics**

Electron microprobe analyses were carried out on the various calcium carbonate fabrics. Chemical compositions of carbonate samples are reported in Table 3 and Figure 7 according to the sample and from...
Carbonates exhibit different Mg and Sr content from one sample to another and from one lamina fabric to the other. For example, sparite calcite contains little Mg (\(\approx 0.05\) wt%) and Sr (\(\approx 0.05\) wt%). It contrasts with Mg-rich drusy calcite (Mg = 0.54 wt%, Sr = 0.05 wt%) and Sr-rich aragonite needles (Mg = 0.08 wt%; Sr = 0.58 wt%) (Table 3).

Carbon, Oxygen, and Strontium Isotope Compositions

Carbon (C) and oxygen (O) isotope compositions were determined on 13 laminae of sample 32 and 6 laminae from sample 33. The results are reported in Table 4 and Figure 8. Sample 32 displays variations in \(\delta^{18}O\) values ranging between –1.22 and –6.13 \(\%\) VPDB and \(\delta^{13}C\) values ranging between –10.75 and –6.52 \(\%\) VPDB. However, the central part of sample

![Detailed microscopic observations of sample 32 based on thin-section SEM chemical maps.](image)

**Zone A** Pore spaces are filled with clays as shown by high concentration of Si, Mg, and Al elements at the transition between laminae 2 and 3. **Zone B** Acicular calcium carbonate is approximately oriented toward the surface and grows from a micritic circular point. A thin film composed of Si, Al, Mg, and O overlies each generation of needle aragonite. **Zone C** The transition between laminae 6 and 7 exhibits a variation from Si- and Mg-rich areas in the dark micritic lamina to Si, Mg, and Al-rich micro-oncoid, together with the occurrence of Si, Mg-rich \(\mu\)m-size grain (serpentine). **Zone D** The sparry calcium carbonate in a pore in lamina 7 is haloed by Mg-Si-rich matrix. This lamina is irregularly thick. Some calcium carbonate crystals are contained in the matrix, the most remarkable example being the rectangular crystal in the dark matrix. A Ca carbonate layer formed over the matrix, first sparry calcite, then intergrown needle-like aragonite with the Si-Mg-rich matrix in contact with a pore. **Zone E** The dark micritic lamina 9 appears to be composed of several rounded carbonates crystals in a Mg-Si-rich matrix.
32 is characterized by a nearly constant $\delta^{18}O$ value with a mean value of $-3.9\%$ (VPDB). Some laminae of sample 33 show an extreme depletion in both $^{13}C$ and $^{18}O$ isotopes, with $\delta^{18}O$ values ranging from $-16.54\%$ to $-10.12\%$ (VPDB) and $\delta^{13}C$ values from $-22.84\%$ to $-12.62\%$ (VPDB).

While the $^{87}Sr/^{86}Sr$ ratio varies between 0.707282 and 0.707994 in sample 32, it is almost constant in sample 33 with a mean value of 0.70821, which is similar to that of hyperalkaline spring at this site (0.708164; Table 4). For sample 32, the most radiogenic Sr isotope ratio

DISCUSSION

Linking Fabrics and Chemical Composition of Travertines

The distinctive fabrics of aragonite and calcite crystals seem to support the primary formation of these minerals (Renaut and Jones 1997). Nevertheless, it is necessary to decipher whether their morphologies express the environmental conditions at which they formed, or if they result from post-formation recrystallization. Divalent cations in aqueous solution (e.g., Mg, Sr, Ba, Mn, and Fe) may substitute for Ca in the crystal lattice during precipitation and recrystallization of carbonate, and when compared to their lamina fabric, can help elucidate primary versus secondary mineral phases. Our approach is based on previous karst waters and speleothem studies which showed that a constant slope in a ln(Sr/Ca) vs. ln(Mg/Ca) plot is due to a low Sr and Mg partition coefficient in calcite (Huang et al. 2001; Fairchild et al. 2000; Fairchild et al. 2006; McMillan et al. 2005; Johnson et al. 2006; Mattey et al. 2009), where dissolved Mg and Sr ions preferentially remain in solution while Ca precipitates as calcium carbonate. This chemical trend applied to speleothems has been named “prior calcite precipitation” (PCP). Based on a worldwide study of speleothems, Sinclair (2011) and Sinclair et al. (2012) were able to distinguish co-variation of Mg, Ca, and Sr concentrations that truly reflect environmental conditions compared to those induced by post-formation recrystallization. When applied to our samples as shown in Figure 7, the average ln(Mg/Ca) and ln(Sr/Ca) ratios of carbonate, without any distinction between carbonate fabrics, plot on or in error bars of the PCP slope (Fig. 7A), suggesting early calcite–water interaction, and not recrystallization.

However, the situation is more complicated when this approach is applied locally to the various carbonate fabrics of a travertine sample. For instance, in sample 28 (Fig. 7B), the dark sparitic lamina plots underneath the PCP slope whereas the white needle-like aragonite fabric plots above the PCP trend towards the range of calcite recrystallization. The combination of fabric and chemical compositions suggests at least partial carbonate recrystallization. Therefore, the geochemical record for climatic reconstruction is less useful for the cemented gravels in sample 28. Alternatively, all of the various carbonate fabrics of sample 32 plot slightly underneath the PCP trend (Fig. 7C), due potentially to different mixing proportions between hyperalkaline springs and runoff waters, which supply significant amounts of Mg and bicarbonate ions in solution compared to lack of supply of Mg from the hyperalkaline waters (Chavagnac et al. 2013b). Here, higher Mg content in carbonates suggests either an increase in runoff water proportion or a reduction of hyperalkaline spring-water influence. Finally, sparite calcite crystals of sample 33, which are formed at the air–water interface, show ln(Mg/Ca) and ln(Sr/Ca) ratios coherent with PCP processes, recording paleo-environmental conditions at the time of their precipitation.

Isotopic Records in Travertine

If well preserved, the carbon and oxygen isotopes can record environmental information in carbonate deposits (e.g., Darling et al. 2005; Lachniet 2009; Brady et al. 2010). The $\delta^{13}C$ values can be used to infer the origin of the carbon source, i.e., atmospheric CO$_2$ and/or DIC.
from runoff waters. The Δ18O is commonly used as a proxy for temperature and rainfall which is controlled by evaporation, condensation, climate, altitude, latitude, and distance from seawater (Dansgaard 1964).

Figure 8 presents the variation in Δ18O values as a function of Δ13C values for all laminae, and depicts two different trends. For sample 32, the Δ18O values remain nearly constant for all laminae, and indicate that hydration and hydroxylation reactions completely buffer the water isotope composition of water (i.e., equilibrium state). Oxygen isotope equilibrium between HCO3\textsuperscript{−} and H\textsuperscript{2}O is achieved, and therefore Δ18O values are not affected by kinetic effects (Mickler et al. 2006). Therefore, it is possible to calculate the equilibrium temperature using the following equation (Grossman 2012 and references therein):

\[ T = 15.7 - 4.36 \times (\delta^{18}O_{\text{carb}} - \delta^{18}O_{\text{water}}) + 0.12 \times (\delta^{18}O_{\text{carb}} - \delta^{18}O_{\text{water}})^2 \]  

(1)

Where \( T \) is temperature (°C), \( \delta^{18}O_{\text{carb}} \) (carbonate) is given relative to the VPDB standard and \( \delta^{18}O_{\text{water}} \) is the oxygen isotope composition of the water (in SMOW) (Table 4). A value of –1.6‰ (SMOW) was chosen for the \( \delta^{18}O_{\text{water}} \) standard, in line with water being a mixture between groundwater from the ophiolite aquifer at ~1.0 to ~1.4‰ (SMOW, Matter et al. 2005) and surface runoff waters at ~1.6 to ~2.4‰ (SMOW, Weyhenmeyer 2000). Sample 32 records wide temperature variations between 14.1 and 37.9°C (mean temperature of 25.4 ± 11°C). The lowest temperature of 14.1°C is striking. Nevertheless, it is not completely inconsistent with a drastic

cooling of 6.5 ± 0.6°C for late Pleistocene Oman groundwaters (Weyhenmeyer et al. 2000). Unfortunately, the lack of sample ages severely restricts the interpretation of these paleo-temperatures in terms of a temporal climatic record.

In contrast, δ18O and δ13C values in sample 33 are close to calcite crust (sparite) values reported in Clark et al. (1992) (Fig. 8). Calcite precipitation is induced by evaporation and atmospheric conversion of gaseous CO2 into carbonated species at the air–water interface. In this context, the coupled depletions in 18O and 13C result from both hydroxylation reactions and kinetic effects based on the difference in diffusion rates of 13CO2 and 12CO2 (Dietzel et al. 1992; Clark et al. 1990).

As a result, stable-isotope compositions alone are seriously limited to assess past climatic conditions without additional information on carbonate fabric and chemical composition. However, δ13C values may be useful to elucidate the sources of carbon supply in this particular DIC-depleted environmental context of travertine formation.

**Hyperalkaline Spring vs. Surface Runoff Waters and the Climatic Record**

Further information about the climatic record may be provided by strontium isotope composition because each geological formation and solution exhibits distinctive 87Sr/86Sr ratios in this region. To confirm a potential contribution of surface runoff waters in travertine formation, the mixing equation of Albarède (1995) was used:

\[
(\frac{87}{86}\text{Sr})_\text{M} = \left( f_A \cdot (\frac{87}{86}\text{Sr})_\text{A} + f_B \cdot (\frac{87}{86}\text{Sr})_\text{B} \right) / \left( f_A \cdot (\frac{87}{86}\text{Sr})_\text{A} + f_B \cdot (\frac{87}{86}\text{Sr})_\text{B} \right)
\]

where A and B stand for two components, i.e., surface runoff and hyperalkaline waters, fA the proportion of component A in the mixture, SrA and SrB are the Sr concentration of components A and B, respectively, and M is a mixture of these two components characterized by (87Sr/86Sr)M isotope composition. In our study, the measured 87Sr/86Sr from each lamina of travertine represents the mixture M. For the calculations, Sr concentrations of 5.7 μmol l–1 and 6.1 μmol l–1 and 87Sr/86Sr ratios of 0.70860 and 0.706686 were taken for surface runoff waters (Weyhenmeyer 2000) and hyperalkaline waters, respectively (Chavagnac et al. 2013b). Sr concentration and isotope composition of hyperalkaline waters are considered constant, as the springs are perennial. The results are presented in Table 4.

Figure 9A illustrates the variation in 87Sr/86Sr ratios, δ18O and δ13C values as a function of laminae thickness throughout sample 32. Strikingly, the Sr isotope signature co-varies with the δ13C values throughout sample 32, whereby the contribution of surface runoff waters varied from 25 to 67%. While the contribution of each end member is almost constant (about 45–50%) in laminae 3 to 7, a 25% decrease is noted at the transition between laminae 7 and 8, where the 87Sr/86Sr ratios decrease from 0.707695 to 0.707282 (Fig. 9). This observation seems to indicate a significant change in the hydrological regime where the contribution from surface water becomes subsidiary to the spring water. This is also sustained by the strong accumulation of Si- and Mg-rich organic material observed in microscopic scale at this transition, suggesting less surface runoff water. In comparison, the co-variation in Sr and C isotope compositions from laminae 8 to 11 indicates an increasing contribution of surface runoff water from 25 to 34% (Fig. 9).

Additionally, the variation in δ18O values of sample 32 are similar to what was obtained for a speleothem in Hoti cave (from −1.39% to −6.13% for sample 32, from −2 to −6% for the Hoti Cave’s speleothem; Burns et al. 2001; Fleitmann et al. 2007). For the speleothem with a constant
temperature in the cave, the reason for such variations of the $\delta^{18}O$ values are interpreted as being due to the northward shift of the ITCZ (Burns et al. 2001; Fleitmann et al. 2007). However, in our study we do not have any temporal constraint of travertine formation; it is therefore difficult to infer with confidence the $\delta^{18}O$ signature of the dominating rain waters. So because neither temperature nor sources are well constrained, in terms of the past climatic record, we can conclude only that the contribution of surface waters in the mixing area has fluctuated through time.

For comparison, all laminae of sample 33 exhibit $^{87}$Sr/$^{86}$Sr ratios very close to the signature of hyperalkaline spring water (i.e., 0.708164), indicating no evidence of mixing with surface waters (Fig. 9B). In contrast, large variations in $\delta^{13}C$ values are observed (between –12.6 and –22.8‰ VPDB, Fig. 9B). In this sample, the kinetic effect induced by the diffusion of CO$_2$(g) at the air–water interface is the major process modifying the C isotope compositions. The unique source of C in sample 33 is atmospheric CO$_2$(g), i.e., a potentially arid climate, as there is no evidence of surface runoff waters based on both $^{87}$Sr/$^{86}$Sr ratios and the link between carbonate fabric and chemical composition.

In summary, the stable-isotope and radiogenic-isotope signatures of laminae document the paleo-activity of hyperalkaline spring waters through time, and contribute to a better understanding of the mechanisms leading to the formation of travertine in a DIC-depleted environment. $^{87}$Sr/$^{86}$Sr ratios have shown to be a useful tracer for quantifying surface runoff water contribution in this setting.

**Fig. 9.—Variations of $\delta^{18}O$ and $\delta^{13}C$ values and $^{87}$Sr/$^{86}$Sr ratio along the A) sample 32 and B) sample 33. Sr-isotope composition of surface runoff water are from Weyhenmeyer 2000.**

**DIC-Depleted vs. DIC-Enriched Environment for Continental Carbonate Formation**

In Oman, the close relationship between the occurrence of travertine and the DIC-depleted hyperalkaline spring waters contrasts radically with most of continental travertines that precipitate from DIC-enriched waters (Capezzuoli et al. 2014). A fundamental question arises from this particular mode of formation: What do the stable-isotope compositions of carbonates record when they are formed in such contrasted DIC environments?

Figure 10 compares the variations in $\delta^{13}C$ and $\delta^{18}O$ values obtained in this study with data presented in the literature and obtained on both DIC-depleted and DIC-enriched environments. Each carbonate deposit defines different fields, although some data from Oman travertines overlap with tufa. All carbonates formed under continental DIC-depleted hyperalkaline conditions define a linear and positive trend between the negative values of $\delta^{13}C$ and $\delta^{18}O$ values. This is in line with the data acquired on carbonate deposits found at the Liguria hyperalkaline waters (Teboul et al. 2016). In addition, carbonates associated with submarine hyperalkaline springs (e.g., the Lost City hydrothermal field located at 30° N along the Mid-Atlantic Ridge, 800 m water depth; Kelley et al. 2001), exhibit positive $\delta^{13}C$ and $\delta^{18}O$ values, at the top end of the linear trend defined by carbonates found at continental DIC-depleted hyperalkaline conditions. Their stable-isotope signature is consistent with marine carbonates, for which the main source of carbon is provided by seawater bicarbonate ions. In general terms, the
variation of stable-isotope signatures reflects the source of carbon supply and the processes that led to carbonate formation, i.e., hydration and hydroxylation reactions and/or diffusion of CO$_2$(g) at the air–water interface, rather than climatic records.

For DIC-enriched environment, Gandin and Capezzuoli (2008) demonstrated that calcareous tufa exhibits negative $\delta^{13}$C and $\delta^{18}$O values that represent outgassing of meteoric and soil derivation (Pentecost 2005) and cool temperature and saturation levels of spring water (Chafetz and Lawrence 1994), respectively. Photosynthetic effects associated with development of microorganisms remained very limited. The C and O stable-isotope compositions reflect the signature of the water from which the calcareous tufa derived, i.e., the local climatic regime. Tufas present negative but intermediate stable-isotope compositions between “DIC-depleted” travertine and calcareous tufa. This reflects the physicochemical signature of karstic water and microorganism activity (Capezzuoli et al. 2014). Finally, “DIC-enriched” travertines are characterized by positive $\delta^{13}$C but negative $\delta^{18}$O values, which illustrate the complex interplay between the source of groundwater thermally heated and tectonic and volcanic activity. In the latter case, little information can be obtained for the past climatic record, but it provides an innovative way to monitor past volcanic carbon dioxide emissions (Capezzuoli et al. 2014).

To summarize, carbonate deposits have a great potential for better defining the physicochemical environmental conditions and the processes that led to their formation. In their study of calcitic–aragonitic travertine–tufa deposits (DIC-enriched environment), Teboul et al. (2016) argue that combining geochemical tracers (Ba and Sr among others) with stable-isotope compositions provide valuable constraints on hydrogeological and paleo-hydrogeological circulation. Based on the present study (DIC-depleted environment), the combination of geochemical tracers with fabric description provides a crucial indicator of crystallization versus recrystallization at the time of carbonate formation, and thus a potential proxy of past environmental conditions. When these observations are combined with isotopic tracers such as O, C, and Sr, then the environmental conditions can be better defined in terms of surface-runoff contribution and source of carbon supply.

Sequestration of Atmospheric CO$_2$ during Travertine Formation

Precipitation rate of travertine from hyperalkaline springs is variable, and will depend on the amount of calcium available, spring flow rate, and temperature, among other parameters (Pentecost 2005). The amount of atmospheric CO$_2$(g) uptake and calcium carbonate amount sequestered in travertine can be estimated either based on the volume and age of the travertine terraces (e.g., Mervine et al. 2014), or from the chemistry and flow rate of spring waters. In the latter case, the assumption is made that calcite precipitation occurs until thermodynamic equilibrium with atmospheric P$_{CO2}$ is reached, or evaporation is total. Calcite was taken as the reference for calculations as it is the main mineral found in travertine (it is also the more stable mineral versus aragonite over geologic time). Volume of calcite precipitate was estimated for sites 28, 32, and 33 based on average chemistry analyses (data from this study and Pentecost 2005) and flow rate at spring (unpublished data), according to the following equation:

$$V_{travertine} = \frac{V_{calc}}{1 - \phi} = \frac{Q \times V_{calc}}{1 - \phi} \int \Delta Ca \, dt$$

\(V_{travertine}\) is the volume of precipitated travertine (which can also be expressed as a rate, i.e., m$^3$ yr$^{-1}$, when divided by time \(t\)), \(V_{calc}\) is the volume of precipitated calcite, \(\phi\) is the porosity of travertine, \(V_{calc}\) is the molar volume of calcite (m$^3$ mol$^{-1}$), and \(\Delta Ca\) is the difference in calcium concentration between the spring ([Ca$\text{aq}$]) and the calcium-depleted solution.
Table 5.—Results of geochemical modeling with CHESS giving an estimate of CO₂ uptake and travertine deposits rate (per year). Input data: [CO₂] = 280 ppm, porosity = 0.35, data of [Ca] from Chavagnac et al. (2013b) and Q from (Chavagnac, unpublished data).

Hypothesis 1: thermodynamic equilibrium is reached

- **CO₂ sequestered (kg yr⁻¹):** 666, 487, 9
- **Vtravertine /t (m³ yr⁻¹):** 8.6, 6.3, 0.1

Hypothesis 2: evaporation is total

- **CO₂ sequestered (kg yr⁻¹):** 817, 522, 15
- **Vtravertine /t (m³ yr⁻¹):** 10.5, 6.7, 0.2

From equilibrium calculations, it appears that the best conditions to store CO₂ as calcium carbonate depend on initial Ca concentration and surface waters mixing with hyperalkaline springs. It seems clear that the rate of sequestration of atmospheric CO₂ also depends on the mechanism of precipitation, which should be accounted for large-scale evaluation.

**CONCLUSION**

A detailed multi-disciplinary approach, from macroscopic to microscopic scale, has been accomplished on three travertine samples formed under DIC-depleted hyperalkaline environments in order to 1) assess the relationship between the petrologic features and fabrics and the geochemical and isotopic signatures, and 2) discuss the potential of these deposits as proxies for past climatic record and sequestration of atmospheric CO₂. The samples illustrate two distinct mechanisms of calcium carbonate formation, either from mixing of hyperalkaline and surface runoff waters (sample 28 and 32) or from dissolution of atmospheric CO₂(g) into hyperalkaline waters (sample 33).

We conclude:

- Travertines as a whole are characterized by chemical compositions, expressed in terms of Mg, Ca, and Sr contents, consistent with “prior calcite precipitation” (PCP) process, i.e., the record of environmental conditions at the time of their formation. However, by comparing trace-element concentrations from one fabric to the other (sparite, drusy, spheroid calcite to aragonite micro-stalactic and needle-like aragonite), it is possible to distinguish between recrystallization conditions (sample 28) and temporal variation of environmental conditions (samples 32 and 33).
- The linear and positive variations in δ¹⁸O and δ¹³C values between laminae reflects two different mechanisms: (1) hydration-hydroxylation reactions from which a paleo-temperature of water can be extracted (sample 32) and/or (2) kinetic effects induced by diffusion of CO₂ at the air–water interface (sample 33).
- The combined variations in O, C, and Sr isotope signatures between laminae document the paleo-activity of hyperalkaline spring and surface runoff waters through formation time scales. The $^{87}$Sr/$^{86}$Sr ratio represents a useful tracer for quantifying surface runoff water contribution, and acts as an indicator of rainfall intensity.
- In the framework of continental carbonates, travertine formed in a DIC-depleted environment exhibit δ¹⁸O and δ¹³C values that contrast to those formed in a DIC-enriched environment. With the prospect of assessing the past climatic record, it appears necessary 1) to combine the detailed petrological observations with chemical compositions at the lamina to unravel crystalization versus recrystallization processes, and 2) to corroborate radiogenic and stable-isotope analyses for quantifying precipitation intensity.
- Finally, the influence of climate should be addressed when quantifying carbonation rates, as shown by the range of CO₂ sequestered in the different scenarios illustrated by our samples (from 9 kg CO₂ yr⁻¹ to 522 kg CO₂ yr⁻¹).

**SUPPLEMENTAL MATERIAL**

**ACKNOWLEDGMENTS**

We acknowledge the technical help of Chantal Perrache (LMV Saint-Etienne) and Michel Thibault, Jonathan Prunier, and Pierre Brunet (GET, Toulouse) for the analyses of O and C isotopes, mineralogical, geochemical, and Sr isotopes, respectively. We also acknowledge the comments of two anonymous reviewers and the editors, which greatly improved the quality and presentation of the data reported in this study.
